Structured abstract, draft

Background. The optimal valve replacement strategy for intermediate surgical risk patients with severe symptomatic aortic stenosis remains debated. We compared one year clinical outcomes after transcatheter and surgical aortic valve replacement across three centers.

Methods. Prospective multi-center cohort. The primary endpoint was the composite of all cause mortality and disabling stroke at twelve months. Secondary endpoints included paravalvular regurgitation, length of stay, and thirty day readmission.

Results. Enrollment is ongoing toward the prespecified target. Final outcome tables will be populated at database lock and adjudication. This title page and abstract accompany the manuscript shell prepared for submission.

Conclusions. To be completed after database lock. The analysis plan and tables are finalized in the manuscript.

Endpoints at a glance

Endpoint	Type	Timepoint
All cause mortality and disabling stroke	Primary composite	Twelve months
Paravalvular regurgitation	Secondary	Discharge and follow up
Length of stay	Secondary	Index admission
Thirty day readmission	Secondary	Thirty days

Submission note

All content is aggregate and de-identified. The completed manuscript with populated outcome tables will follow database lock and adjudication.
